#### **CMPS 2200 – Fall 2017**

**B-trees** 

#### Carola Wenk

# External memory dictionary

**Task:** Given a large amount of data that does not fit into main memory, process it into a dictionary data structure.

- Need to minimize number of disk accesses
- With each disk read operation, read a whole block of data
- Construct a balanced search tree that uses one disk block per tree node
- Each node needs to contain more than one key

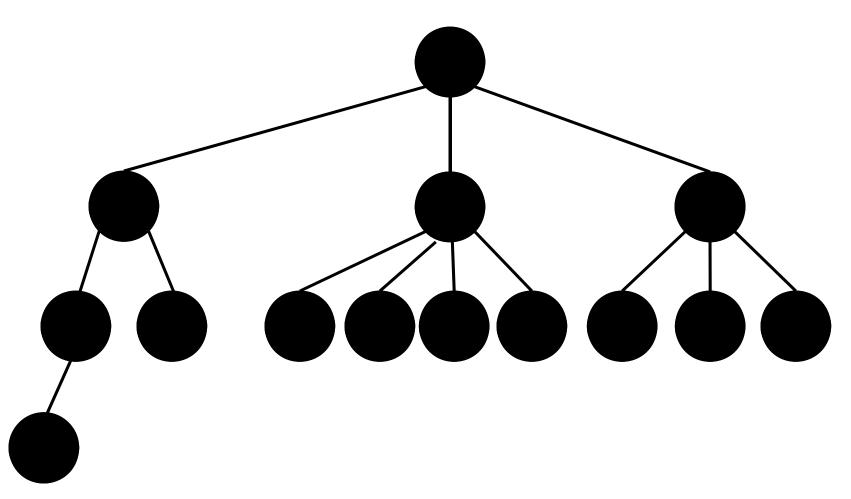

# k-ary search trees

A k-ary search tree T is defined as follows:

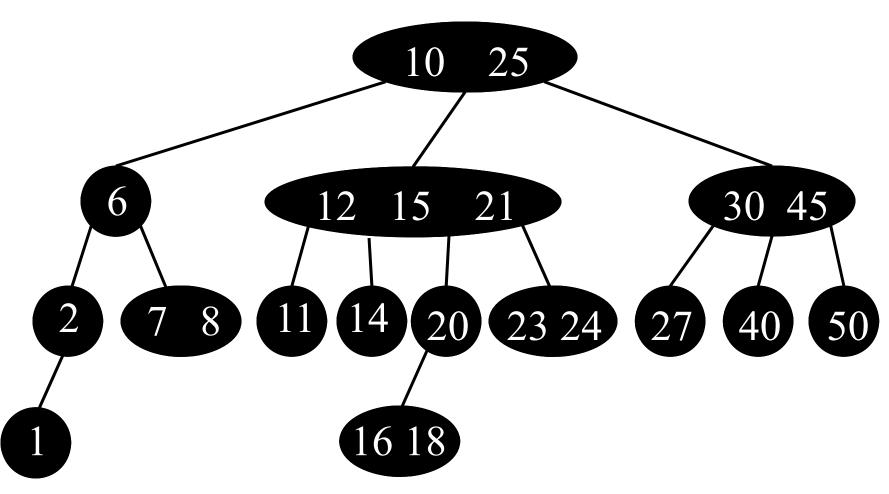

- •For each node *x* of T:
  - x has at most k children (i.e., T is a k-ary tree)
  - x stores an ordered list of pointers to its children, and an ordered list of keys
  - For every internal node: #keys = #children-1
  - x fulfills the search tree property:

keys in subtree rooted at i-th child  $\leq i$ -th key  $\leq$  keys in subtree rooted at (i+1)-st child

# Example of a 4-ary tree

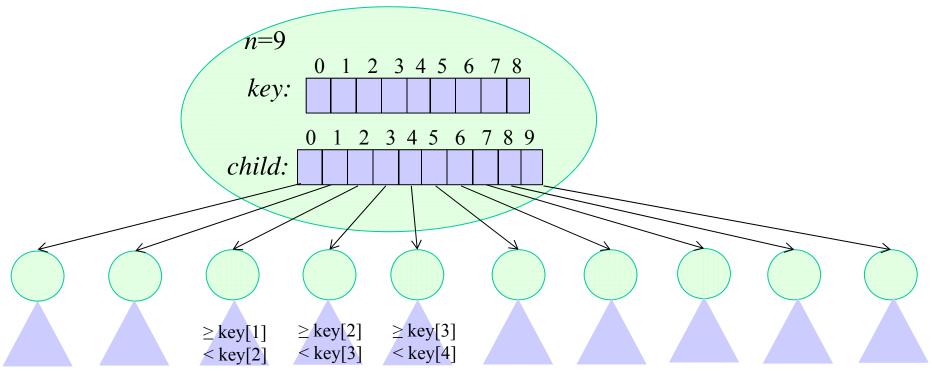

# Example of a 4-ary search tree

### Search Tree Node

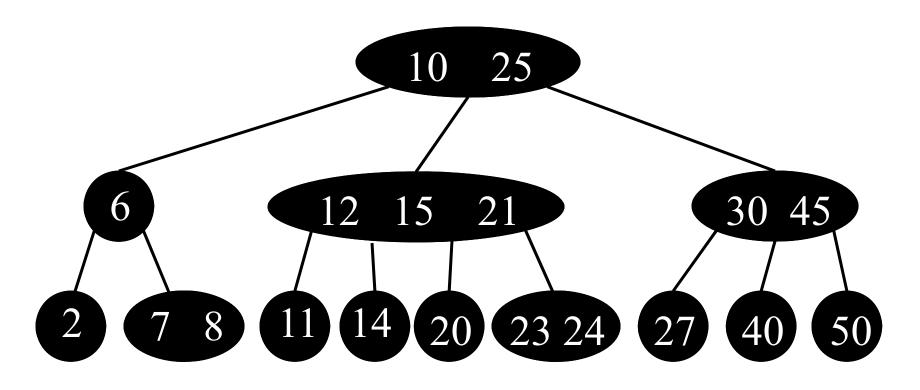

#### TREE-NODE:

```
n// Number of keyskey[0..n-1]// Array of keys stored in non-decreasing// order: key[0] \le key[1] \le ... \le key[n-1]child[0..n]// Array of pointers to children nodes
```

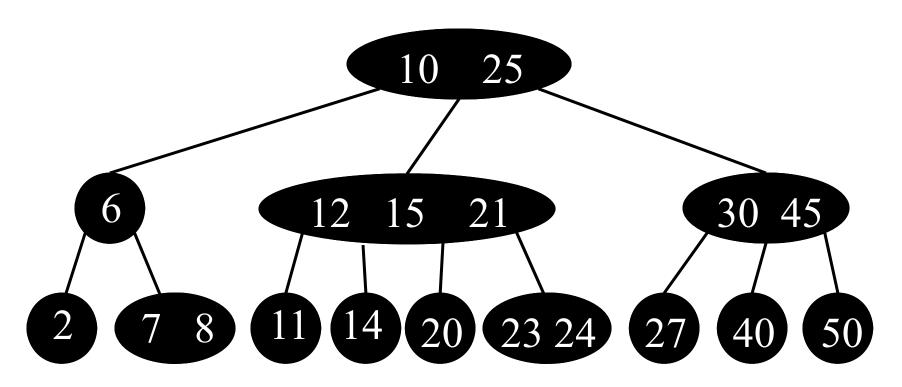

#### **B-tree**

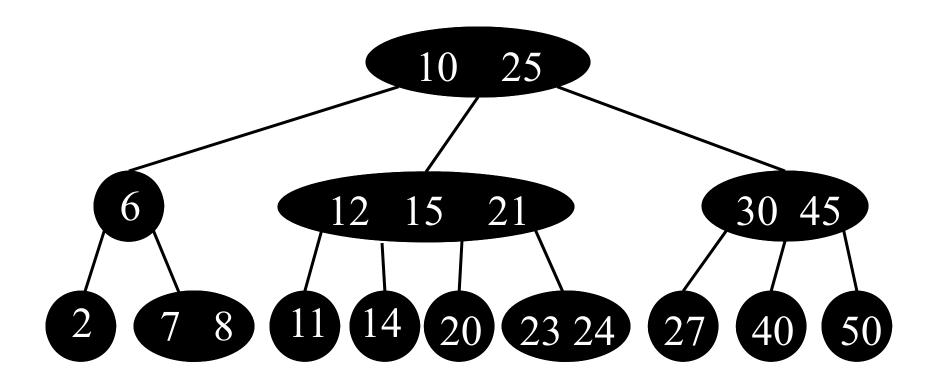

- A *B*-tree T with minimum degree  $k \ge 2$  is defined as follows:
- 1. T is a (2k)-ary search tree
- 2. Every node, except the root, stores at least k-1 keys(every internal non-root node has at least k children)
- 3. The root must store at least one key
- 4. All leaves have the same depth

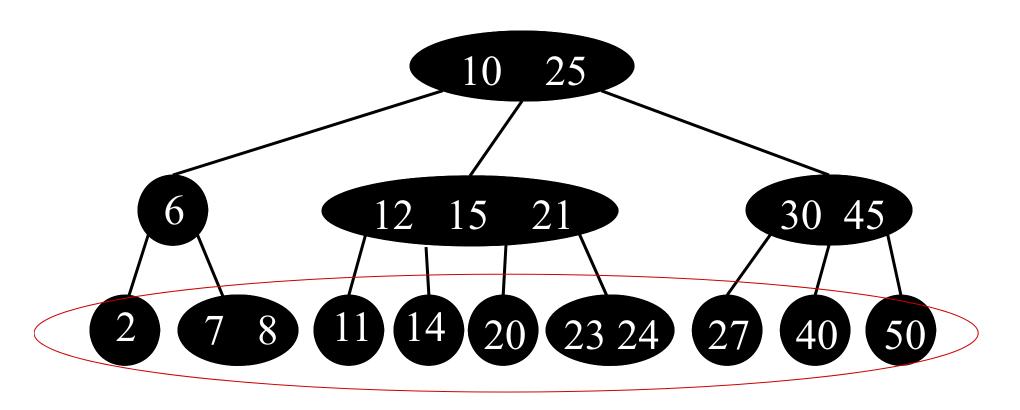

1. T is a (2k)-ary search tree

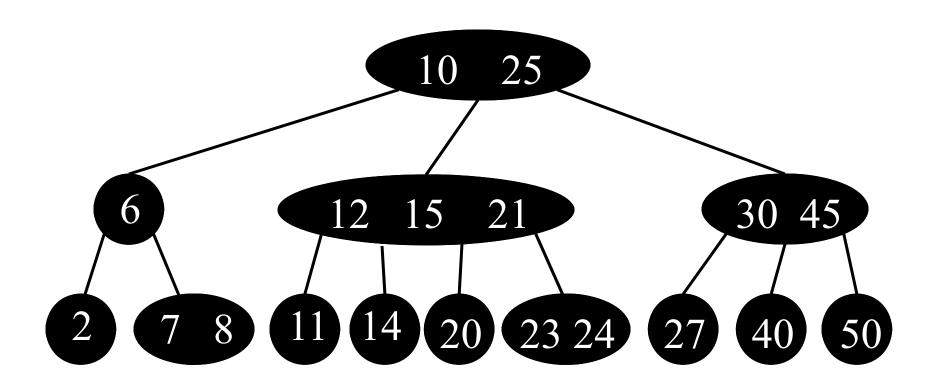

2. Every node, except the root, stores at least *k*-1 keys

3. The root must store at least one key

### 4. All leaves have the same depth

Remark: This is a 2-3-4 tree.

# Height of a B-tree

**Theorem:** For a B-tree with minimum degree  $k \ge 2$  which stores n keys and has height h holds:

$$h \leq \log_k (n+1)/2$$

**Proof:** #nodes  $\geq 1+2+2k+2k^2+...+2k^{h-1}$  level 1 level 3 level 0 level 2

$$n = \#\text{keys} \ge 1 + (k-1) \sum_{i=0}^{h-1} 2k^i = 1 + 2(k-1) \cdot \frac{k^{h-1}}{k-1} = 2k^{h-1}$$

### **B-tree search**

```
B-TREE-SEARCH(x,key) {
    // Search key in node x
    i = 0
    // Find child (subtree) that contains key
    while (i < x.n) \&\& (key > x.key[i])
        i++
    // Found key in node
    if (i < x.n) && (key == x.key[i])
        return (x, i)
    if x is a leaf // key not found
         return null
    else { // Search for key deeper in subtree
        b = DISK-READ(x.child[i])
        return B-TREE-SEARCH(b,key)
```

### B-tree search runtime

- O(k) per node
- Path has height  $h = O(\log_k n)$
- CPU-time:  $O(k \log_k n)$

• Disk accesses:  $O(\log_k n)$ 

disk accesses are more expensive than CPU time

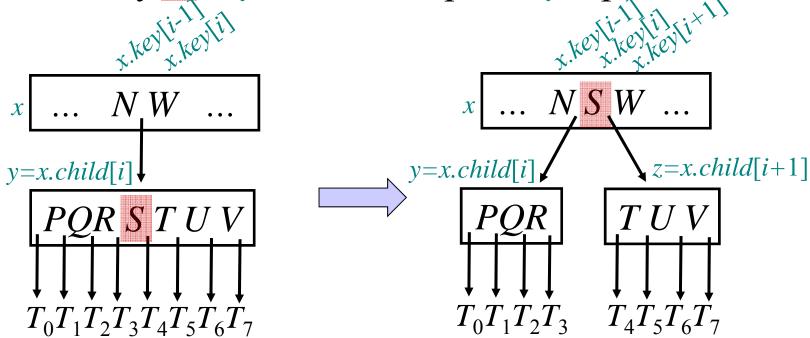

### **B-tree insert**

- There are different insertion strategies. We just cover one of them
- Make one pass down the tree:
  - The goal is to insert the new *key* into a leaf
  - Search where *key* should be inserted
  - Only descend into non-full nodes:
    - If a node is full, split it. Then continue descending.
    - Splitting of the root node is the only way a B-tree grows in height

# B-Tree-Split-Child(x,i)

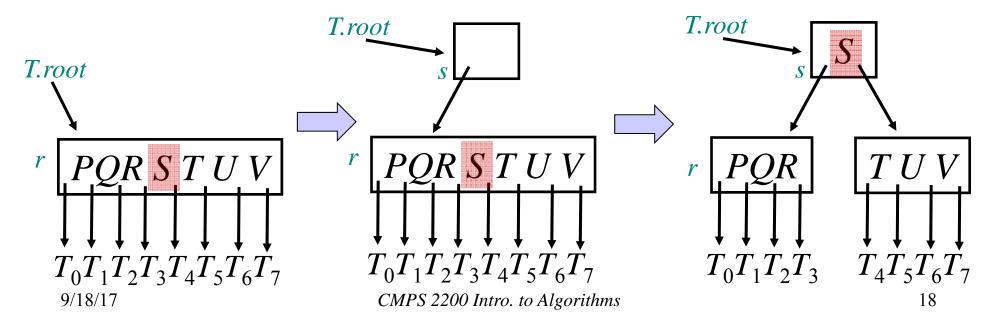

// full node y is *i*-th child of node x

- Split full node  $y \ge 2k-1$  keys) into two nodes y and z of k-1 keys
- Example below for k = 4: Median key S of y is moved up into y's parent x

# Split root: B-TREE-SPLIT-CHILD(s,0)

- A new root node s is created. The **full** root node r is split in two.
- *s* contains the median key *S* of *r* and has the two halves of *r* as children
- Example below for k = 4

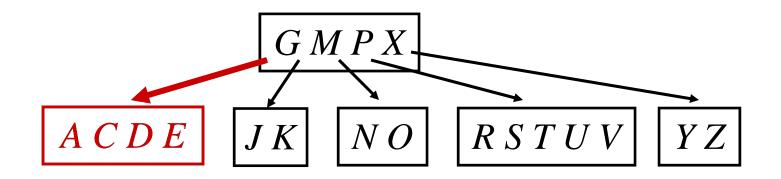

# B-Tree-Insert(T,key)

```
if (T.root.n == 2k-1) // root node is full
    // Insert new root node
    r = T.root
    T.root = ALLOCATE-NODE()
    T.child[0] = r
    // Split old root r to be two children of new root s
    B-TREE-SPLIT-CHILD(T.root,0)
    B-TREE-INSERT-NONFULL(T.root,key)
else
    B-TREE-INSERT-NONFULL(T.root,key)
```

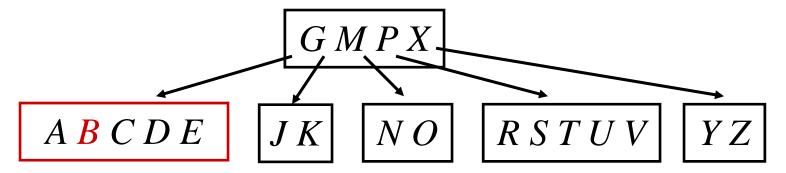

### B-Tree-Insert-Nonfull(x,key)

```
if (x is a leaf) {
    Insert key at the correct (sorted) position in x
    DISK-WRITE(x)
} else {
    c=child of x whose subtree should contain key
    DISK-READ(c)
    if (c is full) \{ // c \text{ contains } 2k-1 \text{ keys} \}
         B-TREE-SPLIT-CHILD(x,i)
         c=child of x whose subtree should contain key
    B-TREE-INSERT-NONFULL(c,key)
```

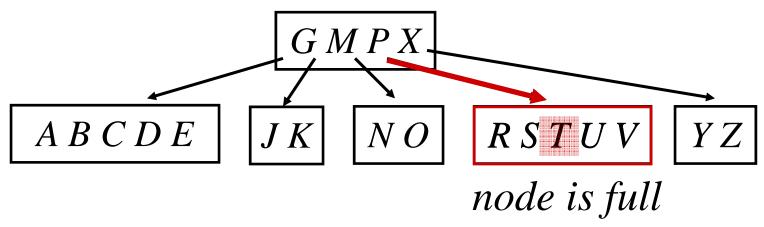

# Insert example (k=3)

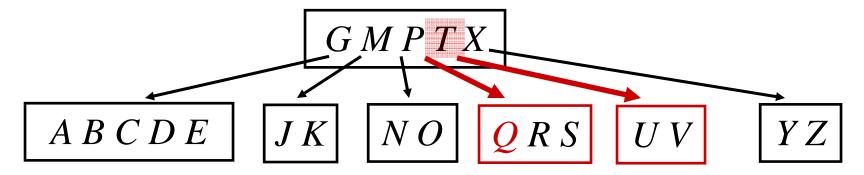

• Insert B:

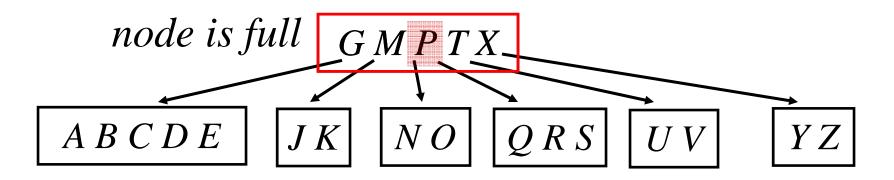

# Insert example (k=3) -- cont.

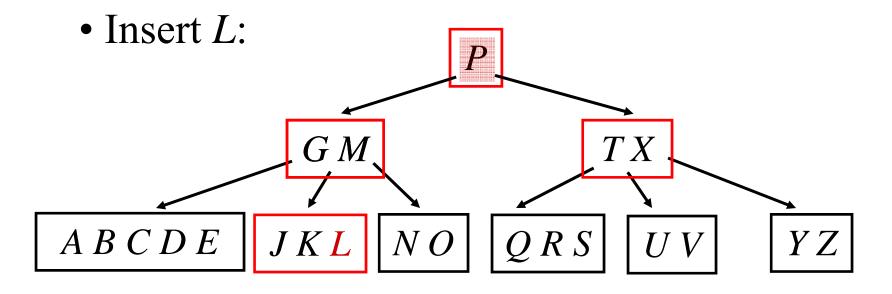

• Insert *Q*:

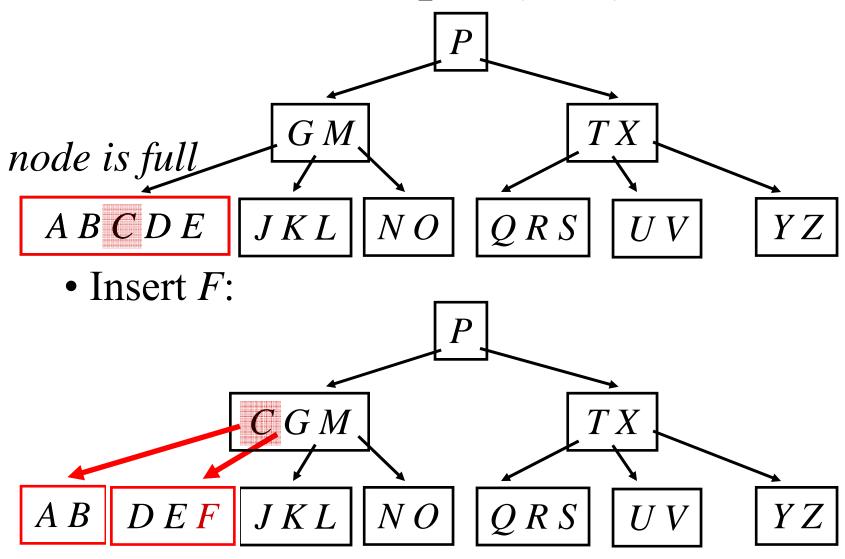

# Insert example (k=3) -- cont.

# Insert example (k=3) -- cont.

## Runtime of B-TREE-INSERT

- *O*(*k*) runtime per node
- Path has height  $h = O(\log_k n)$
- CPU-time:  $O(k \log_k n)$

• Disk accesses:  $O(\log_k n)$ 

disk accesses are more expensive than CPU time

### Deletion of an element

- Similar to insertion, but a bit more complicated
- If sibling nodes get not full enough, they are **merged** into a single node
- Same complexity as insertion

## **B-trees -- Conclusion**

- B-trees are balanced 2k-ary search trees
- The degree of each node is bounded from above and below using the parameter *k*
- All leaves are at the same height
- No rotations are needed: During insertion (or deletion) the balance is maintained by node splitting (or node merging)
- The tree grows (shrinks) in height only by splitting (or merging) the root
